# **A similarity inference method for reducing the cost of pair comparison**

Received: 12 February 2003 / Accepted: 13 May 2004 / Published online: 23 February 2005 © Springer-Verlag London Limited 2005

**Abstract** Group technology must group similar parts into families. In classifying parts based on their global shapes, the similarity of parts has to be manually measured by performing pair comparison. The cost of exhaustively performing pair comparison is quite high when the number of parts to be grouped is large. This paper proposes interval intersection, a novel similarity inference method that effectively infers the pair-comparison data from a set of known data. Justified by empirical experiments, the proposed method outperforms the previous methods when 31% or more of data is known.

**Keywords** Comparison · Group technology · Pair · Set intersection · Similarity inference

# **1 Introduction**

Group technology (GT) is a technique for enhancing design/ manufacturing productivity by grouping similar workpieces into families [1]. Much GT research has been done on the automatic classification of workpieces, which use local features such as holes, steps, and slots as the criteria for justifying similar ity [2–5]. Yet, similarity in local features does not ensure similarity in global shape. These local feature-based GT systems are therefore limited in applications.

Recent GT research aims to develop automatic workpiece classification systems based on the similarity of global shapes [6– 10]. These global-shape-based systems are particularly wellsuited to the application of retrieving similar designs. Yet, automatically characterizing the global shapes of workpieces in

a computational form needs an algorithm, which may not reflect users' recognition model. The effectiveness of such characterization should therefore be justified by user's judgments.

Hsu et al. proposed a full-data benchmarking method for justifying the effectiveness of a global-shape-based GT system [11]. A set of sample workpieces is selected from the general population of workpieces. Then, subjects exhaustively make pair comparisons of the sample workpieces based on their global shape similarity. The full pair-comparison data is used as a benchmark for measuring the effectiveness of an automatic workpiece classification system.

Yet, establishing the full pair comparison data is a timeconsuming and labor-intensive task. Suppose the number of sample workpieces is *n*, and the number of exhaustive pair comparison is  $n(n-1)/2$ . That is, 100 sample workpieces would need about 5,000 pair comparisons. To reduce the number of pair comparison, some research aims to use partial experiment data to infer the full pair-comparison data. For example, of the 5000 pair-comparison data, some studies can use a part of them, say 2000, to infer the remaining 3000 data.

Some similarity inference methods have been developed in the literature [12, 13]. These methods include: (1) the Hamming distance method  $[13, 14]$ ;  $(2)$  the max-min method  $[12, 15]$ ;  $(3)$ the interval average method [12]; and (4) the weighing interval average method [13]. However, these four methods are not accurate enough in inferring the unknown data.

This paper presents a more accurate, similarity inference method, called the interval intersection method. Our experiments show that the interval intersection method outperforms the previous four similarity inference methods in most cases. Thus, the accuracy in inferring the similarity data has been improved.

The remainder of this paper is organized as follows: Section 2 formulates the similarity inference problem and explains how the full pair-comparison data is obtained; Section 3 presents the interval intersection method; Section 4 introduces the previous four inference methods; Section 5 defines three metrics for comparing the effectiveness of the inference methods, and gives their comparison results; and Section 6 offers concluding remarks.

# **2 Problem formulation and experiment data collection**

The problem of similarity inference can be illustrated in the format of a matrix. In Eq. 1, a matrix  $S = [s_{ii}]$   $(1 \le i, j \le n)$  represents the full pair-comparison data of *n* sample workpieces, where  $s_{ij} \in [0, 1]$  denotes the similarity between two objects, *i* and  $j$ . The higher the value of  $s_{ij}$ , the more similar are the two workpieces. Notice  $s_{ii} = 1$  and  $s_{ij} = s_{ji}$  for  $1 \le i, j \le n$ ; here, matrix *S* is symmetric and each of its diagonal elements is 1. Suppose a portion of the matrix elements ( $s_{ij}$  for  $1 \le i \le m$ ;  $i \le$  $j \leq n$ ) is known, the problem of interest is to develop methods to infer the other elements ( $s_{ij}$  for  $m + 1 \le i \le n$ ;  $i \le j \le n$ ). Referring to Eq. 1, the known data is outlined by the trapezoid and the data to be inferred is outlined by the triangle. The inferred matrix is represented by  $\hat{S} = [\hat{s}_{ij}]$ , where  $\hat{s}_{ij} = s_{ij} (1 \le i \le m; i \le j \le n)$ and  $\hat{s}_{ij}(m+1 \le i \le n; i \le j \le n)$  is the inferred data.

$$
S = \begin{bmatrix} 1 & s_{12} & \cdots & s_{1n} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & \cdots & s_{mn} \\ 1 & \cdots & \vdots \\ \vdots & \vdots & \vdots \\ 1 & \cdots & \vdots \\ 1 & \cdots & \vdots \end{bmatrix} . \tag{1}
$$

The full similarity pair comparison data of *n* sample workpieces are collected by the procedure proposed by Hsu et al. [11], which is explained by the example with 36 sample workpieces shown in Fig. 1. The procedure asks 30 subjects (users of the GT system in an aircraft manufacturing company) to make an exhaustive pair comparison. Each subject then has to do 630 (i.e.  $36 \times 35/2$ ) pair comparisons. Each pair comparison is represented in one of the five fuzzy linguistic terms as follows: very high similarity, high similarity, medium similarity, low similarity, very low similarity [16]. Each linguistic term is modeled by a fuzzy number. For each pair comparison, a fuzzy operation is applied to aggregate the 30 fuzzy numbers into one fuzzy number [17]. The aggregated fuzzy number is subsequently converted to a crisp value by a defuzzification process [17]. The  $36 \times 36$  matrix *S* for the sample workpieces can thus be obtained as shown in Table 1.

# **3 Proposed similarity inference methods**

The proposed similarity inference method, the interval intersection method, is presented in this section. The problem of interest is described as follows: suppose  $s_{pq}$  is not known, while  $s_{pi}$  and  $s_{qi}$  are known for some *i*. Herein, the set including such *i* is denoted by *T*. The proposed similarity inference method is to determine  $\hat{s}_{pq}$ .

## **Table 1.** Complete experimental data

#### 3.1 The goal of the algorithm

The goal of the proposed inference method is to estimate  $s_{pq}$ through another workpiece  $k \in T$ . Let  $\hat{s}_{pq(k)}$  denote the estimation of *spq* through workpiece *k*. The upper bound and the lower bound of  $\hat{s}_{pq(k)}$  are respectively represented by  $\hat{s}_{pq(k)}^U$  and  $\hat{s}_{pq(k)}^L$ . The proposed inference method involves a two-step sequence: (1) for each object  $k \in T$ , the bounding interval  $[\hat{s}_{pq(k)}^L, \hat{s}_{pq(k)}^U]$ is first computed (Fig. 2); and (2)  $\hat{s}_{pq}$  is then determined by aggregating the bounding interval  $[\hat{s}_{pq(k)}^L, \hat{s}_{pq(k)}^U]$  for all  $k \in T$ (Fig. 3).

The goal of estimating  $\left[\hat{s}_{pq(k)}^L, \hat{s}_{pq(k)}^U\right]$  is modeling the information contents of the global shape of a workpiece by a set. For a workpiece *p*, the information content of its global shape is represented by the set  $X_p$ , where the area of the set is  $Area(X_p) = 1$ . The similarity between two workpieces  $p$  and  $q$  is the intersection of two sets, that is,  $s_{pq} = Area(X_p \cap X_q)$ .

# 3.2 Deriving the bounding interval of  $\hat{s}_{pq(k)}$

The proposed inference method first computes the bounding interval of  $\hat{s}_{pq(k)}$ ; that is,  $[\hat{s}_{pq(k)}^L, \hat{s}_{pq(k)}^U]$ .

The lower bound of  $\hat{s}_{pq(k)}$  would appear if  $(X_p \cap X_q)$  is made as small as possible. We thus can infer that  $(X_p \cap X_q)$  should be a subset of its relevant sets; that is,  $(X_p \cap X_q) \subset (X_p \cap X_k)$  and  $(X_p \cap X_q)$  ⊂  $(X_q \cap X_k)$ . This further implies that  $\hat{s}_{pq(k)}^L = s_{pk} +$ *skq* − 1 for  $X_p \cap X_q \neq \Phi$ , as shown in Fig. 4a, and  $\hat{s}_{pq(k)}^L = 0$  for  $X_p \cap X_q = \Phi$ , as shown in Fig. 4b. The case in Fig. 4a implies that  $s_{pk} + s_{kq} \ge 1$ , and that in Fig. 4b implies that  $s_{pk} + s_{kq} < 1$ . By integrating the two cases,  $\hat{s}_{pq(k)}^L$  can be computed as follows.

$$
\hat{s}_{pq(k)}^L = Max(s_{pk} + s_{kq} - 1, 0).
$$
\n(2)

**Fig. 2.** Inference of *spq* through  $s_{pk}$  and  $s_{kq}$ , where symbol  $\odot$ represents a similarity inference method

**Fig. 3.**  $s_{pq}$  is inferred by aggregating multiple  $s_{pq(k)}$ , where AGG represents a method of aggregation

**Fig. 4.** Modeling lower bound of  $\hat{s}_{pq(k)}$ 

**Fig. 5.** Modeling upper bound of  $\hat{s}_{pq(k)}$ 

The upper bound of  $\hat{s}_{pq(k)}$  would appear if  $(X_p \cap X_q)$  is made as large as possible. We can thus infer that( $X_p \cap X_q$ ) is not a subset of its two relevant sets; that is,  $(X_p \cap X_q) \not\subset (X_p \cap X_k)$ , and  $(X_p \cap X_q)$  ⊄  $(X_q \cap X_k)$ . This further implies that  $\hat{s}^U_{pq(k)} = s_{qk} +$  $(1-s_{pq})$  when  $s_{pk} \geq s_{kq}$ , as shown in Fig. 5a, and  $\hat{s}^{U}_{pq(k)} = s_{pk} +$  $(1-s_{kq})$ , when  $s_{pq} < s_{qk}$  as shown in Fig. 5b. By integrating the two cases in Fig. 5,  $\hat{s}^U_{pq(k)}$ can be computed as follows:

$$
\hat{s}_{pq(k)}^U = 1 - |s_{pk} - s_{kq}|.
$$
\n(3)

#### 3.3 Aggregation of bounding intervals

For each object  $k \in T$ , there exists a bounding interval  $[\hat{s}_{pq(k)}^L,$  $\hat{s}^{U}_{pq(k)}$ ] for  $\hat{s}_{pq(k)}$ . Let  $[\hat{s}^{L}_{pq}, \hat{s}^{U}_{pq}]$  denote the bounding interval of  $\hat{s}_{pq}$ , which can be computed by the following aggregation procedure (where the individual bounding intervals are aggregated by the set intersection operation):

$$
[\hat{s}_{pq}^L, \hat{s}_{pq}^U] = \bigcap_{k \in T} [\hat{s}_{pq(k)}^L, \hat{s}_{pq(k)}^U] = [Max \hat{s}_{pq(k)}^L, Min \hat{s}_{pq(k)}^U].
$$

 $\hat{s}_{pq}$  is subsequently estimated as follows:

$$
\hat{s}_{pq} = \frac{\hat{s}_{pq}^U + \hat{s}_{pq}^L}{2} \quad \text{if } \hat{s}_{pq}^L \le \hat{s}_{pq}^U \text{ (i.e., } [\hat{s}_{pq}^L, \hat{s}_{pq}^U] \neq \Phi) \n\hat{s}_{pq} = 0 \quad \text{if } \hat{s}_{pq}^L > \hat{s}_{pq}^U \text{ (i.e., } [\hat{s}_{pq}^L, \hat{s}_{pq}^U] = \Phi) .
$$

## 3.4 Example

The following example is used to illustrate the inference method. The example includes five sample workpieces: the first two rows  $(m = 2)$  of the *S* matrix, the known data, is denoted by  $S_2$ ; and the last three rows of the *S* matrix, the unknown data, are to be inferred.

$$
S_2 = \left[ \begin{array}{rrr} 1 & 0.4 & 0.3 & 0.4 & 0.2 \\ 1 & 0.7 & 0.7 & 0.3 \end{array} \right].
$$

According to the above inference method,  $\hat{s}_{34(1)}^L =$ Max  $(0.3 + 0.4 - 1, 0) = 0$  and  $\hat{s}_{34(1)}^U = 1 - |0.3 - 0.4| = 0.9$ . Therefore,  $[\hat{s}_{34(1)}^L, \hat{s}_{34(1)}^U] = [0, 0.9]$ . Likewise,  $[\hat{s}_{34(2)}^L, \hat{s}_{34(2)}^U] =$  $[\text{Max } (0.7 + 0.7 - 1, 0), 1 - [0.7 - 0.7]] = [0.4, 1].$  Then,  $[\hat{s}_{34}^L, \hat{s}_{34}^U] = [0.4, 0.9]$  and  $\hat{s}_{34} = \frac{0.4 + 0.9}{2} = 0.65$ .

Accordingly, the symmetric matrix  $\hat{S}$  can be estimated by the interval intersection method as follows:

$$
\hat{S} = \begin{bmatrix} 1 & 0.4 & 0.3 & 0.4 & 0.2 \\ 1 & 0.7 & 0.7 & 0.3 \\ 1 & 0.65 & 0.3 \\ 1 & 0.3 & 1 \end{bmatrix}.
$$

# **4 Previous inference methods**

4.1 The Hamming distance method

The formulas for estimating  $\hat{s}_{pq}$  by the Hamming distance method [13, 14] are described below:

$$
\hat{s}_{pq(k)} = 1 - |s_{pk} - s_{qk}|
$$
\n
$$
\hat{s}_{pq} = \frac{\sum_{k \in T} \hat{s}_{pq(k)}}{h},
$$
\nwhere *h* denotes the total number of objects in set *T*.

Taking the example in Sect. 3.4, we can infer that  $\hat{s}_{34(1)} = 1 |0.3-0.4| = 0.9$ ,  $\hat{s}_{34(2)} = 1 - |0.7-0.7| = 1.0$ , and  $\hat{s}_{34} = (1.0 +$  $(0.9)/2 = 0.95$ . By the Hamming distance method, matrix S is computed as follows:

$$
\hat{S} = \begin{bmatrix} 1 & 0.4 & 0.3 & 0.4 & 0.2 \\ 1 & 0.7 & 0.7 & 0.3 \\ 1 & 0.95 & 0.75 \\ 1 & 0.7 & 1 \end{bmatrix}.
$$

#### 4.2 The max-min inference method

The max-min similarity inference method [12, 15] is introduced below:

 $\hat{s}_{pq(k)} = \text{Min}(s_{pk}, s_{kq})$  $\hat{s}_{pq} = \text{Max}_{k \in T} (\hat{s}_{pq(k)})$ .

Taking the example in Sect. 3.4, we can infer that  $\hat{s}_{34(1)} =$  $\min(0.3, 0.4) = 0.3$ ,  $\hat{s}_{34(2)} = \min(0.7, 0.7) = 0.7$ , and  $\hat{s}_{34} =$ max  $(0.3, 0.7) = 0.7$ . By the max-min method, matrix *S* is computed as follows:

$$
\hat{S} = \begin{bmatrix} 1 & 0.4 & 0.3 & 0.4 & 0.2 \\ 1 & 0.7 & 0.7 & 0.3 \\ 1 & 0.7 & 0.3 \\ 1 & 0.3 & 1 \end{bmatrix}.
$$

#### 4.3 The interval average method

The interval average method [13] is introduced below:

$$
\hat{s}_{pq(k)} = \frac{\hat{s}_{pq(k)}^L + \hat{s}_{pq(k)}^U}{2}
$$

$$
\hat{s}_{pq} = \frac{\sum_{k \in T} \hat{s}_{pq(k)}}{h}.
$$

where *h* is the total number of objects in set *T*.

Taking the example in Sect. 3.4, we can infer that  $\hat{s}_{34(1)} =$  $(0+0.9)/2 = 0.45$ ,  $\hat{s}_{34(2)} = (0.4+1) = 0.7$ , and  $\hat{s}_{34} = (0.45+1)$  $(0.7)/2 = 0.575$ . By the interval average method, the matrix *S* is computed as follows:

$$
\hat{S} = \begin{bmatrix} 1 & 0.4 & 0.3 & 0.4 & 0.2 \\ & 1 & 0.7 & 0.7 & 0.3 \\ & & 1 & 0.575 & 0.375 \\ & & & 1 & 0.35 \\ & & & & 1 \end{bmatrix}.
$$

#### 4.4 The weighting interval average method

The weighting interval average method [13] is introduced below:

$$
\hat{s}_{pq(k)} = \frac{\hat{s}_{pq(k)}^L + \hat{s}_{pq(k)}^U}{2}
$$
\n
$$
\hat{s}_{pq} = \frac{\sum_{k \in T} \hat{s}_{pq(k)} \times [1 - (\hat{s}_{pq(k)}^U - \hat{s}_{pq(k)}^L)]}{\sum_{k \in T} [1 - (\hat{s}_{pq(k)}^U - \hat{s}_{pq(k)}^L)]}.
$$

Taking the example in Sect. 3.4, we can infer that  $\hat{s}_{34(1)} =$  $(0 + 0.9)/2 = 0.45$ ,  $\hat{s}_{34(2)} = (0.4 + 1) = 0.7$ , and  $\hat{s}_{34} =$  $\frac{0.45 \times 0.1 + 0.7 \times 0.4}{0.1 + 0.4}$  = 0.65. By the weighted interval average method, the matrix *S* is computed as follows:

$$
\hat{S} = \begin{bmatrix} 1 & 0.4 & 0.3 & 0.4 & 0.2 \\ & 1 & 0.7 & 0.7 & 0.3 \\ & & 1 & 0.65 & 0.33 \\ & & & 1 & 0.33 \\ & & & & 1 \end{bmatrix}.
$$

# **5 Metrics and comparison**

As mentioned above, the data to be inferred in matrix *S* in*volves*  $s_{ij}$  for  $m + 1 \le i \le n$ ;  $i \le j \le n$ . Define  $R = \{(i, j) | m +$  $1 \leq i \leq n; i \leq j \leq n$ . Then,  $s_{pq}$  is an element to be inferred  $\forall (p, q) \in R$ . For these matrix elements to be inferred, we would prefer that  $\hat{s}_{ij}$  is as close to  $s_{ij}$  as possible. The following sections define three metrics to compare the effectiveness or accuracy of the above five inference methods.

### *(A) Mean absolute deviation*

The first metric, mean absolute deviation (MAD), is defined below:

$$
MAD = \frac{\sum_{(p,q)\in R} |s_{pq} - \hat{s}_{pq}|}{r}
$$
 (4)

where *r* denotes the total number of elements in set *R*.

#### *(B) Root mean square*

The second metric, root mean square (RMS), is defined below:

$$
RMS = \sqrt{\frac{1}{r} \sum_{(p,q)\in R} (spq - \hat{s}pq)^2}
$$
 (5)

where *r* denotes the total number of elements in set *R*.

#### *(C) Percentage of small deviation range*

Let *A* and *B* be two sets defined as follows:

*A* = { $\hat{s}_{pq}$  | | $s_{pq} - \hat{s}_{pq}$ | ≤ 0.1}  $B = \{\hat{s}_{pa} \mid |s_{pa} - \hat{s}_{pa}| > 0.1\}$ 

The third metric, PSD (percentage of small deviation) indicates the percentage of "good" inference, and is defined as follows:

$$
PSD = \frac{N(A)}{N(A) + N(B)}\tag{6}
$$

where  $N(A)$  denotes the number of elements in set  $A$ ,  $N(B)$  denotes the number of elements in set *B*.

Of the three metrics, the MAD and RMS measure the degree of accuracy for a similarity inference method. The smaller the two metrics, the higher the accuracy of estimation. The metric PSD measures the percentage of "good inference". The higher the PSD, the higher is the accuracy of estimation.

### 5.2 Comparison

The 36 workpieces shown in Fig. 1 are taken to compare the effectiveness of the five similarity inference methods. The full pair comparison data, the  $36 \times 36$  symmetric matrix *S*, is shown in Table 1. As stated, a portion of the matrix elements *sij* for  $1 \leq i \leq m$ ;  $i \leq j \leq n$  is known, and the other elements  $s_{ij}$  for  $m +$  $1 \leq i \leq n$ ;  $i \leq j \leq n$  is to be inferred. Table 2 shows the percentage of known data for different *m* values.

Table 3 depicts the MAD, Table 4 shows the RMS, and Table 5 describes the PSD for the five similarity inference methods. The proposed interval intersection method outperforms the other four methods in the three metrics when 31% or more data is known. Notice that when only 6% data is known, the pro-

**Table 5.** PSD of the five inference methods

posed method is inferior to the max-min method. Yet, in such a scenario (where only 6% data known), the inferred results are not so "good". Table 5 shows that only 49.6% of the data inferred by the max-min method is "good". The table also shows that when 56% of data is known, 74.6% of inferred data (by the interval intersection method) is "good".

To ensure a reasonably accurate inference about pair comparison, according to the experiment, the known data had better be more than 56% or more. The proposed interval intersection method is the best choice for such an inference.

# **6 Conclusions**

Building the pair comparison similarity matrix for a group of objects is helpful to some applications such as group technology. However, manually performing pair comparisons is quite timeconsuming and labor-intensive.

This paper proposes interval intersection, a similarity inference method that can be used to infer the unknown data from a set of known data. According to three metrics, MAD, RMS and PSD, the proposed method is compared with the previous four methods in literature. Experiments show that the proposed method outperforms the other four when 31% or more data is known. The proposed method is inferior to the max-min method when only 6% data is known. Yet, when only 6% data is known, only about 50% of inferred data is "good". To ensure a reasonably accurate inference, the proposed interval intersection method is the best choice to date.
