Abstract

A chemical bath is shown to deposit an IrO₂ film on an ITO substrate. The chemical bath is prepared by mixing an Ir precursor $(Na_3IrCl₆ \cdot xH₂O)$, an oxidizer (NaClO), a complexing agent (NaNO₂), and a complex agent/stabilizer (NaOH) in an aqueous solution at a molar ratio of 1:1.5:10:30. From the UV–vis absorption spectra, complexes such as $[\text{Ir(OH)}_6]m^{3-}$, $[\text{Ir(NO)}_2)_4\text{Cl}_2]^3$ ⁻, and $[\text{Ir(NO)}_2)_3\text{Cl}_3]^3$ ⁻ are identified. These complexes are relatively stable, minimizing the undesirable homogeneous precipitation of $IrO₂$ nanoparticles in favor of the heterogeneous growth of the IrO₂ film on the ITO substrate. Diffraction patterns from the as-deposited IrO₂ film reveal an amorphous structure. In addition, profiles from X-ray absorption spectroscopy and X-ray photoelectron spectroscopy indicate that the oxidation state of the Ir in the as-deposited IrO₂ film is $+4$. Thermogravimetric analysis confirms the inclusion of 10 wt% hydrated water in the as-deposited IrO₂ film. Scanning electron microscope images reveal a continuous solid film with a smooth surface. The amorphous $I\text{rO}_2$ film becomes rutile $I\text{rO}_2$ phase after a mild heat treatment in air.

Keywords: Iridium oxide; Thin film; Chemical bath deposition; Indium tin oxide

1. Introduction

The synthesis of iridium oxides has received considerable attention because iridium oxide has many unique properties that make it an ideal material for applications in electrochromism [\[1,](#page-6-0)[2\]](#page-7-0), bio-sensing [\[3](#page-7-0)–[8\]](#page-7-0), and water electrolysis [\[9](#page-7-0)–[14\]](#page-7-0). To date, methods including thermal decomposition [\[15](#page-7-0)–[17\]](#page-7-0), sputtering deposition [\[13,18](#page-7-0)–[20\],](#page-7-0) pulsed laser deposition [\[21\]](#page-7-0), and electrodeposition [\[6](#page-7-0)–[9,11](#page-7-0),[22,23\]](#page-7-0) have been explored for the fabrication of desirable nanoscale iridium oxide structures, such as thin films and nanoparticles. Thermal decomposition and sputtering deposition involve complex instrumentation, including heating and vacuum setups. Electrodeposition involves the use of suitable complexing agents in the plating bath to stabilize the iridium precursors (Ir^{3+}) and Ir^{4+}), which are known

ppwu@mail.nctu.edu.tw (P.-W. Wu).

to undergo spontaneous redox reactions triggered by photons [\[24\]](#page-7-0). In addition, electroplating techniques require a conductive substrate to serve as the working electrode, preventing the deposition of iridium oxide films on insulators.

An alternative solution for the synthesis is chemical bath deposition, in which the iridium precursors undergo oxidation reactions initiated by selectively incorporated oxidizers. This approach does not require externally imposed current/voltage and allows semiconducting materials to be used as the substrates for film growth [\[25](#page-7-0)–[28\]](#page-7-0). So far, several studies have reported the formation of iridium oxide nanoparticles and investigated their electrocatalytic properties for oxygen evolution reactions in water splitting experiments [\[9](#page-7-0)-[11](#page-7-0),[13](#page-7-0),[14,22,29](#page-7-0)-[31\].](#page-7-0) However, these studies failed to describe the formation mechanisms of the iridium oxide and instead focused on material characterizations and performance evaluations. On the other hand, iridium oxide is a biocompatible electrode material which have been investigated to replace platinum to enhance the efficiency [\[32](#page-7-0)–[34\]](#page-7-0). However, the preparation of iridium oxide traditionally uses

^{*}Corresponding author. Tel.: +886 3 5131227; fax: +886 3 5724727. E-mail addresses: st1019@gmail.com (P.-C. Chen),

sputtering process and consumes unnecessary noble target [\[6,7\]](#page-7-0). In addition, aspect ratio of the substrate is limited for the sputtering process. Therefore, chemical bath deposition does not require applying voltage/current or conducting substrates, so iridium oxide film can be coated on various materials, such as Si, $SiO₂$, and ITO, under ambient environments. Moreover, chemical bath deposition is a relatively cost efficient process because there is no extra precursor consumed, and it has better capability to coat iridium oxide onto targeting substrate. In order to better use, it is recognized that the surface composition, structure, and morphology play critical roles in determining the resulting properties. Hence, it is necessary to better understand and have control over the fabrication process to synthesize iridium oxides with desirable properties.

In the chemical bath used to form iridium oxides, the addition of complexing agents is necessary to inhibit unwanted redox reactions among the iridium precursors. Among the explored complexing agents, the hydroxide ions are often used to facilitate the synthesis of iridium oxide nanoparticles by stabilizing the iridium ions in the form of $[Ir(OH)₆]²$; they also aid in hydrolysis and acid-catalyzed condensation, as well as precipitation reactions [\[12](#page-7-0),[14,23,30,35](#page-7-0),[36\]](#page-7-0). This process provides a facile route to prepare nanoparticulate iridium oxides but is ineffective for the deposition of iridium oxide thin films. Therefore, in addition to hydroxide ions, it is necessary to identify additional complexing agents to strengthen the stability of the complexed iridium ions and thus extend the lifetime of the plating bath, allowing heterogeneous precipitation to occur selectively on the intended substrates.

In this study, we demonstrate a formulation for the deposition of iridium oxide films $(IrO₂)$ on an indium tin oxide (ITO) substrate *via* a chemical bath deposition route in which $IrCl₆³$ is used as the Ir precursor, hydroxide ions (OH^{-}) are used as the stabilizer and complexing agent, and nitrite ions $(NO₂⁻)$ and hypochlorite ions (CIO^-) are employed as the complexing agent and the oxidizer, respectively. The reaction steps responsible for $IrO₂$ formation are explored, and the material characterizations of the resulting thin films are discussed.

2. Experimental

2.1. Preparation of chemical bath

A glass slide coated with ITO (Aldrich; 8–12 Ω/sq) over an area of 2.5×2.5 cm² was utilized as the substrate for the chemical bath deposition. The thickness of the ITO coating was 120–160 nm. Prior to the deposition, the ITO substrate was rinsed with deionized water and acetone to remove any debris and contaminants. The deposition bath contained 0.0474 g (1×10^{-4} mol) Na₃IrCl₆ $\cdot xH_2O$ (Aldrich), 5.5674 g $(1.49 \times 10^{-4} \text{ mol})$ NaClO (SHOWA), 0.12 g $(3 \times 10^{-3} \text{ mol})$ NaOH (Mallinchrodt), and 0.069 g (1×10^{-3} mol) NaNO₂ (SHOWA). The $Na₃IrCl₆ · xH₂O$ and NaClO were utilized as the precursor and oxidizer, respectively. The $NaNO₂$ was used as the complexing agent for the Ir precursor. The NaOH was used both as the complexing agent for the Ir precursor and the stabilizing agent for NaClO. A schematic of the preparation of the chemical bath and the deposition process is depicted in Fig. 1. First, $Na₃IrCl₆ · xH₂O$ was dissolved in deionized water, forming a pale yellow solution. Another transparent mixture was prepared by separately dissolving $NaNO₂$, $NaOH$, and NaClO in deionized water, and then these three solutions were mixed together. Once the Ir precursor solution was added to the transparent mixture, the resulting solution turned light yellow and was kept at 25° C for 10 min. Subsequently, the light yellow solution was placed in a water bath at $70 \degree C$ for another 10 min, allowing the complexed Ir precursors to react with the oxidizer to form a dark blue solution. At this stage, the solution was ready for deposition, and the ITO substrate was immersed for 3 h to allow the growth of $IrO₂$.

2.2. Materials characterization

A UV–vis spectrometer (JASCO V-670) was used to record the absorption spectra of the deposition bath at 70° C. A highresolution X-ray diffractometer (XRD; Bruker D8 Discover) with a Cu K α radiation source of 1.54 Å was employed to identify the phase and crystallinity of the $IrO₂$. Thermogravimetric analysis (TGA) was employed to determine the hydration

Fig. 1. An experimental flowchart of the processing steps for the $IrO₂$ deposition. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

state of the Ir deposit. For the TGA measurements, nitrogen (40 mL min^{-1}) and argon (60 mL min^{-1}) were used as the balance and sample gas, respectively, and the heating rate was maintained at 3° C min⁻¹. A particle sizer (Beckman Coulter Delsa™ Nano C particle analyzer) was used to determine the ζpotential of the suspended nanoparticles in the bath. An X-ray photoelectron spectrometer (XPS; Thermo Microlab 350) with an Mg target was used to identify the oxidation state of the Ir deposits. Prior to the XPS measurements, additional Pt was sputtered onto the $IrO₂$ surface to supply a correction standard for the binding energy of Pt $4f_{7/2}$. The film surface was bombarded with Ar ions at 3 kV and 1 μA for 30 s prior to recording the XPS signals. A field-emission scanning electron microscope (FE-SEM; JEOL-JSM-6500F) with a 15 keV operating voltage was used to observe the morphology and thickness of the deposited film.

X-ray absorption spectroscopy (XAS) of the Ir L_{III} -edge was used to determine the chemical nature of the Ir in both the deposition bath and the deposited film. The XAS spectra were obtained from the BL17C1 and BL01C1 beam lines at the National Synchrotron Radiation Research Center at Hsinchu, Taiwan, and the standard operating conditions were 1.5 GeV and 300–360 mA. The photon energy was calibrated using the L_{III} -edge of a metallic Ir foil, and the XAS data were recorded in a fluorescence mode at 25° C in air. A Zn foil was utilized as a fluorescence filter for the photons entering the fluorescence detector. The resulting spectra were processed by a program (Athena, version 0.8.056) in which the Ir L_{III} -edge absorption steps were normalized to unity with removal of the background signals. Because the film was deposited on an ITO substrate, no reference signal was collected from the reference chamber. Therefore, the self-prepared Ir and $IrO₂$ films were used as the standards for the X-ray absorption near-edge structure (XANES). These self-prepared standards were fabricated using identical deposition time and formulation, but the as-deposited films were subjected to additional heat treatments in hydrogen $(30\%H₂/70\%Ar$ for 30 min) and air (30 min) , respectively. The detailed XAS experimentation and analysis process has been reported elsewhere [\[37\]](#page-7-0).

3. Results and discussion

We performed the chemical bath deposition at 70° C to accelerate the deposition rate; at 25° C, the light yellow solution required at least 48 h to transition to dark blue and become ready for deposition. Notably, once the solution appeared dark blue in color, colloids of $IrO₂$ were deposited heterogeneously only onto the ITO substrate. There was no $IrO₂$ coated onto $SiO₂$ side of the substrate because there was a very slow etching of $SiO₂$ in alkaline solution. In addition, IrO₂ was precipitated homogeneously throughout the solution. The presence of both homogeneous and heterogeneous precipitates was not unexpected because similar phenomena have been reported in previous studies [\[12](#page-7-0),[36](#page-7-0),[38\].](#page-7-0) Because the bath at 70° C was relatively unstable, neither sensitization nor activation of the ITO substrate was required, simplifying the deposition process and reducing the likelihood of contamination.

Fig. 2 displays the in-situ UV–vis spectra of the deposition bath at 70° C. From 0 to 10 min, a broad absorption peak located at approximately 300 nm and a minor peak at 350 nm were observed, and their intensities increased progressively with time. At this stage, the color of the deposition bath was light yellow. The absorption peak at 300 nm was attributed to $[\text{Ir}(\text{OH})_6]^3$ ⁻, and the minor absorption peak at 350 nm was associated with $[\text{Ir}(\text{NO}_2)_4\text{Cl}_2]^3$ ⁻ and $[\text{Ir}(\text{NO}_2)_3\text{Cl}_3]^3$ ⁻. The assignments of these absorption peaks show that these complexes were the most kinetically stable complexes of Ir in similar formulations. After 10 min at 70 \degree C, we observed the formation of precipitates in conjunction with a decrease in the absorption peak at 300 nm. This observation indicates that the concentration of $[\text{Ir}(\text{OH})_6]^3$ ⁻ decreased continuously upon precipitation. In addition, the precipitate formation produced a notable increase in the absorption intensities for the wavelengths below 250 nm. These increases were due to the scattering effect of the suspended precipitates. [Table 1](#page-3-0) summarizes the results from a literature survey of the UV–vis absorption peaks observed from various Ir precursors in solution. Importantly, the increase and decline of the 300 nm absorption peak in Fig. 2 suggests the complexation of Ir^{3+} by OH^- ligands and their subsequent removal to form IrO₂. In contrast, the absorption peak at approximately 350 nm experienced only a subtle change in intensity, suggesting that the $NO₂⁻$ ligands formed stronger Ir complexes. We believed that the OH^- ligands were more easily oxidized by the NaClO to produce $IrO₂$ than the $NO₂⁻$ ligands because the reduction of the absorption peak at 350 nm was moderate compared with that at 300 nm.

Once the precipitation process began, the overall background absorption intensity increased steadily due to the scattering of the dark blue nanoparticles. To verify the role of the OH^- ligands in the deposition bath, we prepared a solution containing the Ir precursors, OH^- , and NaClO, and studied its absorption profile as a function of time [\(Fig. 3](#page-3-0)). In

the absence of $NaNO₂$, we could better elucidate the hydrolysis and condensation process of the Ir precursors. Upon the formation of $[Ir(OH)₆]³$, a minor absorption peak at 570 nm appeared, in addition to the strong absorption peak at 300 nm. Over the past two decades, numerous studies have suggested that the absorption peak at 570–590 nm arises due to the formation of $IrO₂$ colloids [\[22](#page-7-0),[36,39\].](#page-7-0) However, we believe that Ir dimer complexes or oligomers may also contribute to this peak because they are readily produced in aqueous solutions [\[29\]](#page-7-0). Recent studies have also indicated that these Ir complexes can exist as dimers or oligomers, and act as intermediates prior to the formation of IrO₂ [\[29,38](#page-7-0),[40\].](#page-7-0)

[Fig. 4](#page-4-0) depicts the XANES spectra for the Ir L_{III} -edge from the as-deposited film and the Ir precursor solutions at 25° C prior to the formation of the colloidal nanoparticles. For the XAS L-edge absorption profiles, the magnitude of the absorption intensity indicates the available vacant states in the d-orbitals, and its magnitude is therefore proportional to the oxidation state of the absorbing atoms [\[41\]](#page-7-0). [Fig. 4](#page-4-0)(a) provides the XANES spectra and [Fig. 4](#page-4-0)(b) shows an enlargement of spectra. The absorption profile of the aqueous Ir precursor solution $(Na_3IrCl_6 \cdot xH_2O;$ labeled as (i) in the legend) served as the standard for Ir^{3+} . The XAS signals from the as-deposited film (labeled as (ii) in the legend) and the self-prepared $IrO₂$ (labeled as (iii) in the legend) exhibited a strong resemblance, suggesting that the oxidation state of Ir in the as-deposited film was Ir^{4+} . Interestingly, the reflection points for the as-deposited film $(11,216.4 \text{ eV})$ and self-prepared IrO₂ (11,216 eV) were rather close. We also prepared solutions of NaNO₂, NaOH, and NaClO (labeled as (iv), (v), and (vi) in the legend) and determined that the oxidation states of the Ir contained in them were between Ir^{3+} and Ir^{4+} . During the data collection for the XAS spectra, minor precipitation of $IrO₂$ may have occurred, even at 25° C. Therefore, it was expected that these solutions simultaneously contained Ir complexes (Ir^{3+}) and IrO₂ nanoparticles (Ir⁴⁺), rendering an averaged Ir oxidation state between Ir^{3+} and Ir^{4+} . Solution (iv) contained the iridium precursors and NaNO_2 but lacked OH^- and was pale yellow in color. The pale yellow solution, with a pH of 4.04, remained stable for over a month at 25° C. This result suggests that the Ir

Fig. 3. UV–vis spectra from the reference bath at $70\degree C$ as a function of time. The reference bath contained $Na₃IrCl₆ · xH₂O$, NaClO, and NaOH.

complexes with the $NO₂⁻$ ligands and forms a very stable complex in aqueous solution, with subdued heterogeneous nucleation and growth. In contrast, solution (v), which consisted of the iridium precursor, NaClO, and NaOH, was able to deposit IrO₂ on the substrate. However, in this formulation, rapid homogeneous precipitation led to the notable appearance of suspended nanoparticles. Solution (vi) displayed a moderate Ir oxidation state, indicating that the solution contained stable $NO₂⁻$ coordinated complexes and IrO₂ colloids. It has been reported that nitrite ions $(NO₂⁻)$ are able to replace $Cl⁻$ ligands to form nitroiridate complexes in aqueous solution, with the most kinetically stable ions being $trans-[Ir(NO₂)₄Cl₂]³⁻$ and $fac-[Ir(NO₂)₄Cl₂]³⁻$ $(NO₂)₃Cl₃$ ³⁻. This result suggests that the presence of $NO₂$ complexes inhibited the rapid $IrO₂$ colloid formation. In short, based on our observations, the introduction of OH^- and $NO_2^$ ligands into the Ir precursor solution markedly improved the lifetime of the resulting deposition bath and significantly reduced homogeneous precipitation.

In our formulation, the molar ratio of $Na₃IrCl₆ · xH₂O$: NaClO:NaOH:NaNO₂ was 1:1.5:30:10. As mentioned in the

Fig. 4. The XANES spectra for the Ir L_{III}-edge from the as-deposited film and the Ir precursor solutions at 25° C prior to the formation of the colloidal nanoparticles. (a) Ir L_{III} -edge XANES spectra of (i) Na₃IrCl₆ aqueous solution; (ii) self-prepared IrO₂; (iii) the as-deposited IrO₂ film; (iv) aqueous solution of $Na₃IrCl₆$ and NaNO₂; (v) aqueous solution of Na₃IrCl₆, NaNO₂, and NaOH; and (vi) aqueous solution of Na₃IrCl₆, NaNO₂, NaOH, and NaClO (the IrO₂ plating bath). (b) spectra enlargement of (a). The profiles were recorded at 25 °C prior to the formation of colloidal precipitates. The self-prepared IrO₂ was obtained by subjecting the as-deposited $IrO₂$ film to thermal annealing in ambient atmosphere for 30 min. The resulting XRD pattern confirmed the formation of crystalline $IrO₂$.

experimental section, to prepare the deposition bath, all chemicals except the Ir precursors were mixed together in deionized water at 25° C. Once the Ir precursors were added, the $NO₂⁻$ ions coordinated to the Ir ions, replacing the Cl⁻ ligands and resulting in the formation of nitroiridate(III) ions. It has been reported that $[Ir(NO₂)₄Cl₂]³⁻$ and $[Ir(NO₂)₃Cl₃]³$ are the most kinetically-stable species among the nitroiridate (III) ions, as listed in Eq. (1) below. As the temperature of the deposition bath was increased to 70° C, due to the presence of OH^- and the elevated temperature, ligand exchange occurred, leading to a predominance of pale yellow $\left[\text{Ir}(\text{OH})_6\right]^3$ ions and

a minor presence of dark blue Ir oligomers, as listed in Eq. (2) below. It is recognized that the Ir oligomers might undergo hydrolysis reactions to produce $IrO₂$, as listed in Eq. (6). However, we believed that the extent of the hydrolysis reactions from the Ir oligomers was relatively minor because of the slow formation rate of the oligomers, as discussed in [Fig. 3](#page-3-0) (relative to the rate of formation of the predominant [Ir $(OH)_{6}$]³⁻). Due to the presence of a strong oxidizing agent (hypochlorite ions), the ClO⁻ oxidized the Ir³⁺ complexes, including $[Ir(OH)₆]³⁻$, $[Ir(NO₂)₄Cl₂]³⁻$, and $[Ir(NO₂)₄Cl₂]³⁻$, producing iridium oxide, as outlined in Eqs. (3)–(5), respectively. The iridium oxides produced from these deposition reactions contained oxygen defects, making the expected chemical formula IrO₂. Eq. (3) was expected to proceed faster than Eq. (4) and Eq. (5). In the control solution, which did not contain NO_2^- (contained the Ir precursor, NaOH, and NaClO only), we observed the steady formation of bubbles in the solution, which were most likely $Cl_{2(g)}$. This Cl_2 formation was attributed to the relatively slow reaction rates of Eq. (4) and Eq. (5) compared with the stronger and more rapid $NO₂$ coordination to the Ir centers. In addition, among the proposed equations, Eq. (2) and Eq. (3) are the most kinetically favorable due to the facile complexing ability of the OH ligands. Between $NO₂⁻$ and $OH⁻$, the former exhibits a stronger electron affinity, which resulted in greater electron transfer from the Ir ions and the stable coordination between the $NO₂⁻$ ligands and the Ir ions. The overall reaction route is depicted in Fig. 5.

Fig. 5. A schematic of the reaction paths involved in the deposition of the IrO₂ film.

Fig. 6. The XRD patterns of (a) as-deposited $IrO₂$ film, (b) ITO substrate, (c) heat-treated IrO₂ film, and (d) suspended precipitates filtered from the plating bath.

Fig. 6 provides the XRD patterns of the as-deposited film, the ITO substrate, the heat-treated $IrO₂$ film, and the suspended precipitates filtered from the plating bath. The patterns of the as-deposited film and the ITO substrate exhibited a remarkable similarity, suggesting that the diffraction peaks of the asdeposited film resulted entirely from the ITO substrate (cubic In_2O_3 , JCPDS 01-071-2194). In addition, compared with the standard $IrO₂$ pattern (JCPDS 00-043-1019), none of the characteristic diffraction peaks associated with rutile $IrO₂$ were observed. The crystallinity of the $IrO₂$ film was further improved simply by subjecting the as-deposited film in a heat treatment at 500 $^{\circ}$ C for 30 min in air. The as-deposited film was amorphous but after the heat treatment, the $IrO₂$ became a crystalline rutile phase (shown in Fig. 6(c)). The grain size estimated from Scherrer's equation for the rutile $IrO₂$ (1 1 0) phase at 27.9 ° is 18.47 nm. Therefore, we concluded that the as-deposited film was amorphous in nature. The pattern from the suspended precipitates exhibited no apparent diffraction peaks, as shown in Fig. 6(d). This result suggested that the suspended precipitates were amorphous $IrO₂$. The suspended precipitates underwent further zeta potential measurements, revealing a ζ-potential of 3.86 \pm 4.97 mV. This low ζ-potential value indicates relatively weak repulsive forces among the colloids, which led to moderate aggregation and a more rapid deposition rate following the initial nucleation stage. Notably, the deposited sample contained hydrated $H₂O$, and according to TGA analysis, a weight loss of 10% occurred under 200 °C. This 10% weight loss was attributed to the hydrated H_2O in the amorphous $IrO₂$ film.

Fig. 7 displays the XPS profiles of Ir 4f and O 1s. The signals from commercial iridium materials such as Ir, $IrO₂$, and $IrO_2 \cdot xH_2O$ were utilized as the standards for the spectra. As depicted in Fig. 7(a), the binding energy of Ir was located at 63.41 and 60.44 eV for Ir $4f_{5/2}$ and $4f_{7/2}$, respectively. Fig. 7(b) reveals that the binding energy of O 1s was positioned at 530.4 eV. [Table 2](#page-6-0) provides the binding energy of Ir and O for the standards and the as-deposited sample.

Fig. 7. XPS signals from the as-deposited $IrO₂$ film for (a) Ir 4f and (b) O 1s.

Through comparison with the signals from the commercial metallic iridium and iridium oxides, it is apparent that the oxidation state of Ir in the as-deposited film was approximately Ir⁴⁺. Because the doublet signals (4f_{5/2} and 4f_{7/2}) from Ir were close in value, the curve fit to the iridium 4f level for composition determination exhibited substantial uncertainty. [Table 2](#page-6-0) also lists the oxygen signals from the standards and the as-deposited film, which suggest that the as-deposited film was close in oxidation state to $IrO₂$. The XPS profile from the $IrO₂·nH₂O$ standard contained oxygen signals from both metal oxides and hydrated water. This result confirms that the oxygen in the as-deposited film was correctly assigned to the oxygen atoms in the metal oxides rather than the oxygen atoms in the hydrated water. That is to say, the as-deposited film contained less hydrated water than commercial IrO₂ nH_2O . This finding is consistent with the TGA result discussed above.

		Ir		O

	IrO ₂ \cdot nH ₂ O	63.67	61.21	531.42
Sample	As-deposited film	63.41	60.44	530.40

Table 2 Binding energies of Ir and O as determined by XPS.

Fig. 8. FE-SEM images of the as-deposited $IrO₂$ film on an ITO substrate in (a) planar and (b) cross-sectional views.

Fig. 8 presents the FE-SEM images of the as-deposited $IrO₂$ films on an ITO substrate in planar and cross-sectional views. The surface morphology was relatively smooth, as shown in Fig. 8(a), and measurements from atomic force microscopy determined an average roughness of 3.55 nm. It can be observed that the film was possibly formed by the coalescence of individual nanoparticles into larger islands. In the crosssectional view which is shown in Fig. 8(b), the average film thickness was only 39 nm. The as-deposited film was found to be continuous, as pinholes and voids were not observed. The film quality of the as-deposited film in our work is similar to those reported in the literatures. For example, Cruz et al. employed an electrodeposition process to deposit amorphous IrO_x on a Pt-coated glass, and the as-deposited film revealed a granular morphology [\[5\].](#page-7-0) In addition, Zhao et al. electroplated a colloidal IrO_x film on a fluorine-doped tin oxide substrate and observed a granular morphology on the surface [\[22\].](#page-7-0) In addition, Steegstra and Ahlberg demonstrated identical granular surface from the electroplated $IrO₂$ on a gold substrate [\[29\].](#page-7-0) It seems that the granular microstructure is rather common for IrO_x film derived from the electrochemical route. It is also noted that after the minor heat treatment in air, the morphology for the crystalline rutile $IrO₂$ film was similar to the as-deposited amorphous film.

4. Conclusions

We developed a formulation to deposit $IrO₂$ films on an ITO substrate. The deposition bath contained aqueous solution of $Na₃IrCl₆ · xH₂O$, NaNO₂, NaClO, and NaOH. From the UV– vis absorption spectra, we identified the presence of $[Ir(OH)₆]$ x^{3-} , [Ir(NO₂)₄Cl₂]³⁻, and [Ir(NO₂)₃Cl₃]³⁻ in the deposition bath. These complexes enabled an improved lifetime by minimizing homogeneous precipitation in favor of the heterogeneous growth of the $IrO₂$ film. The XRD patterns from the as-deposited $IrO₂$ film revealed an amorphous structure but a crystalline rutile $IrO₂$ film was formed after a mild heat treatment. In addition, the XAS and XPS results suggested the oxidation state of the Ir in the as-deposited film was Ir^{4+} . TGA analysis confirmed the inclusion of 10 wt% hydrated water in the as-deposited $IrO₂$ film. SEM images demonstrated a continuous solid film with moderate surface roughness. According to this study, more applications of $IrO₂$ can be investigated by coating it on various kind/ shape of substrates, such as $TiO₂$ and $Al₂O₃$ microprobes, via this chemical bath deposition method [\[6,7](#page-7-0),[31,42\]](#page-7-0).

Acknowledgements

The financial supports from the National Science Council (NSC100-2221-E009-075-MY3; 103-3113-P-008-001) and the Biomedical Electronics Translational Research Center (BETRC) of National Chiao Tung University are greatly appreciated.
